## Task 1:

5:

Based on spatial locality, the nested loop with columns inside, col\_inner.c, will perform
faster, because 2D arrays are retrieved by row, not column. This is because 2D arrays are
stored by one row following another, and column really just acts like an index on each
row.

6:

| # of rows | Average Execution Time for | Average Execution Time for |
|-----------|----------------------------|----------------------------|
|           | col_inner.c                | row_inner.c                |
|           |                            |                            |
| 10        | 0                          | 0                          |
| 100       | 0                          | 0                          |
| 1000      | 0                          | 0                          |
| 10000     | 0.483                      | 0.997                      |
| 50000     | 12.304                     | 30.629                     |

## 7:

- Execution time increases when the size of the array the loops are iterating through, like one would expect. Strangely, it does not increase linearly, and in fact, there appears to be no time taken by the function until the array has 10,000 rows and columns, and then it appears to be half a second. And then it grows exponentially from 10,000 to 50,000.
- The prediction was correct, col\_inner.c performed better than row\_inner.c.
- With arrays of smaller sizes, it may take such a small amount of time that the clock function can not accurately measure the execution time. When trying to figure out this problem, I printed the start and end clocks, both of which read to be 0, so it is most likely because the programs are executed too quickly.
- Each implementation was executed multiple times because the times can vary. The times can vary because most operating systems now are multi-tasking, and the execution time can vary depending on if the program runs into other processes on the computer during its execution, which could affect run time.

## Task 2:

• The cache sizes are as follows:

L1d cache: 32K
 L1i cache: 32K
 L2 cache: 256K
 L3 cache: 30720K

- The RAM size is 515722.
- Cache sizes influence execution time, because the bigger the cache, the more memory
  that is immediately accessible by the CPU, which means less time is spent trying to
  access memory.

Task 3:

To get the cache hits I used:

\$perf stat -e cache-references ./executable\_name

To get the cache misses I used:

\$perf stat -e cache-misses ./executable\_name

The cache hits and misses indicate the efficiency of the program. The more misses a program has, the longer it takes because it has to take more time accessing memory.

When a program needs to access data not in the cache, or when its attempt to access data results in a cache miss, it retrieves a spatial locality from the memory, or data that is stored close together. So if a program uses data that is stored close together, like two values next to eachother in an array, the program will have more cache hits, because when retrieving the first element, the program also retrieves the other element from memory.

| col_inner     |            |              |  |
|---------------|------------|--------------|--|
| Size of array | Cache hits | Cache misses |  |
| 10            | 3,291      | 1,818        |  |
| 100           | 3295       | 2,196        |  |
| 1000          | 3,839      | 2,249        |  |
| 10000         | 59,653     | 8,351        |  |
| 50000         | 7,630,365  | 72,489       |  |

| row_inner     |               |              |  |
|---------------|---------------|--------------|--|
| Size of array | Cache hits    | Cache misses |  |
| 10            | 3,181         | 2,172        |  |
| 100           | 3,518         | 2,260        |  |
| 1000          | 76,657        | 7,022        |  |
| 10000         | 106,341,240   | 5,171,072    |  |
| 50000         | 5,353,559,731 | 483,972,500  |  |
